163 Chapter 1

164 Introduction

165 Every dissertation should have an introduction. You might not realize it, but the
166 introduction should introduce the concepts, backgrouand, and goals of the dissertation.

167

Part I

168

Theoretical Motivations and the

169

Standard Model

170 Chapter 2

171 The Standard Model and Beyond

172 2.1 The Standard Model

173 The pinnacle of humanities ability to represent the fundamental fields and particles
174 that build the universe, the Standard Model is the guiding theoretical basis of particle
175 physics.

176 2.2 Quantum Chromodynamics

177 Quantum chromodynamics is super wack

178 **2.3 Quantum Electrodynamics**

179 Quantum Electrodynamics is the first model created in the QFT image.

180 **2.4 Spontaneous Symmetry Breaking**

181 Spontaneous symmetry breaking occurs when a system loses an inherent symmetry in
182 order to attain a lower energy configuration.

183 **2.5 The Higgs Mechanism**

184 The Higgs Mechanism is the system by which particles attain mass through the spon-
185 taneous breaking of the Higgs potential, thus causing all particles it interacts with to
186 have mass.

187 **2.6 Parton Distribution Function**

188 Before QFT the proton was thought to be a hard ball containing no smaller constituents.
189 However, we know now that that the strong field inside the proton allows for any strong
190 object to exist with some probability which changes based off of the total energy of the
191 proton. This behavior is represented then by a Probability Distribution Function.

192

Part II

193

Experimental Apparatus and

194

Associated Facilities

195 Chapter 3

196 The Large Hadron Collider

197 Located 100 meters under the Swiss / French boarder lies the 26.7 kilometer Large
198 Hadron Collider (LHC) [1]. The culmination of a huge international collaboration,
199 this apparatus is used to produce proton and heavy ion collisions for observation by the
200 four major experiments at the LHC: ATLAS, CMS, LHCb, and ALICE. The system was
201 designed for a maximum center-of-mass energy of $\sqrt{s} = 14$ TeV and a peak instantaneous
202 luminosity of $L = 10^{34} \text{cm}^{-2} \text{s}^{-1}$.

203 The first LHC workshop was held in 1984 in Lausanne at the European Organization
204 for Nuclear Reserach (CERN) [2]. The nearly 30 year old case for a machine that
205 would push towards the discovery of the elusive Higgs Boson was presented using the
206 existing CERN accerlerator facilities and the Large Electron Positron (LEP) collider
207 tunnel. The proposal became reality on September 10, 2008 when the first proton beams
208 were circulated, only to have calamity strike 9 days later in the form of a catastrophic

209 electrical fault. The repairs and improvements lasted until November 2009 when the
210 LHC restarted. Since then this modern marvel has worked wonderfully and, as hoped,
211 lead to the discovery of the Higgs Boson by the CMS and ATLAS collaborations July
212 4, 2013.

213 The following chapter provides a brief introduction to the worlds most powerful accel-
214 erator starting with the little red bottle of hydrogen in building XXX, and ending with
215 the interaction point where protons collide at the highest energies ever produced.

216 **3.1 Particle Injecton Chain**

217 We begin with the most common element in the Universe, hydrogen, as our source of
218 protons. A bottle of hydrogen gas provides 100 microsecond pulses of raw H_2 which
219 is then injected into a Duoplasmatron. There, a strong electric field and free elctrons
220 from a cathode ionize the molecule into bare H^+ aka a proton! These protons are
221 then accelerated by a 90kV field, leaving the Duoplasmatron with 1.4% speed of light
222 ($\sim 4000\text{km/s}$) or, in relativistic units, about 83KeV. The bare protons are then fed
223 into the accelerating RadioFrequency (RF) cavities of Linear Accelerator 2 (LINAC2).
224 Inside, conductors charged by a powerful oscillating electromagnetic field accelerate the
225 protons resulting in a 50MeV energy. Along the way, small quadrupole magnets shape
226 the proton packet insuring they remain in a tight beam. This pattern of accleration
227 with RF cavities and shaping/turnig with magnets is then repeated with CERN's first

Figure 3.1: CERN accelerator complex

228 synchrotron, the Proton Synchrotron (PS) rendering a 1.4 GeV beam. The final step
229 before the LHC comes with the Super Proton Synchrotron where the same technologies
230 are implemented to produce 450 GeV protons, ready for injection into the LHC. A
231 diagrammatic representation of this chain can be seen in figure 3.1

232 In order to produce proton-proton collisions the LHC uses two beams circulating in
233 opposite directions. The beams are not continuous, but instead consist of bunches, or
234 buckets, of $\mathcal{O}(10^{11})$ protons with a spacing of 25ns. Given the LHC circumference this
235 allows for 3564 buckets, however only 2808 are filled per beam due to safety requirements
236 and injection limitations. Each beam takes 4 minutes and 20 seconds to fill and then an
237 additional 20 minutes to for the protons to reach their maximum energy of 7 TeV TeV,
238 or 99.99999991% the speed of light! Under normal operating conditions these beams
239 can be used for many hours.

240 **3.2 LHC layout and design**

241 While often depicted as a perfect circle the LHC is in reality an octagon with rounded
242 edges, called arcs, as can be seen in figure 3.2. Here you can see the counter circulating
243 beams of protons depicted in red and blue. These beams are focused and collided at
244 the 4 dedicated interaction points at rates of up to 40 MHz. Two of these points are
245 occupied by the ATLAS and CMS experiments, both of which are high luminosity,
246 multi-purposed experiments.

Figure 3.2: Labeled diagram of all the experiments at the LHC indicating the counter circulating beams and points of interest along the circumference of the accelerator.

247 The exact design of the tunnel is due to the experimental constraints of the original
 248 machine for which it was built, the Large Electron Positron (LEP) Collider. For the
 249 $\sim 2,000$ times lighter electron the maximum energy was limited by the synchrotron
 250 radiation, proportional to $\frac{1}{m^4}$, requiring long straight sections of accelerating RF cavities
 251 to recouperate the lost energy. Given that this effect is $\mathcal{O}(10^{13})$ times smaller for the
 252 proton the LHC is instead limited by our ability to design and construct magnets strong
 253 enough to bend the beam given the already determined curvature of the 8 arcs.

Figure 3.3: Depiction of a LHC dipole magnet 2-in-1 design labeling the major components

254 The oppositely circulating beams must each have their own ring and magnetic field
255 which lead to the creation of a twin-bore (i.e. "two-in-one") magnet design, a cross
256 section of which can be seen in figure 3.3. These magnets are constructed using NbTi
257 superconductors which are cooled to 2K using superfluid helium. These magnets are
258 designed to provide the needed 8.33 T magnetic field required to bend the beams at the
259 design beam energy of 7 TeV. In total 1231 of these 15 m long bending dipole magnets
260 are used, in association with 392 5-7m long quadrupole magnets which are responsible
261 for keeping the proton bunches in a tight beam by squeezing them either horizontally
262 or vertically.

263 **3.3 Performance**

264 Since the begining of its stable running in 2010 the LHC has performed well, even
265 exceeding our expectations. While the experiment itself is incredibly complex, the
266 performance of the machine, for the purposes of our analysis, can be reduced to two
267 numbers; the familiar center of mass energy of the beams and a less common quantity
268 known as the integrated luminosity.

269 For particle physics the integrated luminosity is proportional to the total number of
270 collisions recorded during a specified time period, while the instantaneous luminosity is
271 proportional to the bunch crossing rate along with the cross section of a proton-proton
272 interaction and represents the potential number of collisions per second. Knowing this

we can see that the integrated luminosity, L_{int} is simply the integral of the instantaneous luminosity $L_{inst.}$ for a choosen data period as seen in equation 3.1.

$$L_{int} = \int L_{inst.} dt \quad (3.1)$$

For a standard Gaussian beam, $L_{inst.}$ can be written as

$$L = \frac{N_b^2 n_b f_{rev} \gamma_r}{4\pi \epsilon_n \beta^*} F \quad (3.2)$$

where N_b is the number of particles per bunch, n_b the number of bunches per beam, f_{rev} the revolution frequency, γ_r the relativistic gamma factor, ϵ_n the normalized transverse beam emittance, β^* the beta function at the collision point, and F the geometric luminosity reduction factor due to the crossing angle at the interaction point given by

$$F = \left(1 + \left(\frac{\theta_c \sigma_z}{2\sigma^*} \right)^2 \right)^{-1/2} \quad (3.3)$$

where θ_c is the full crossing angle at the interaction point, σ_z is the RMS bunch length, and σ^* is the transverse RMS beam size at the interaction point.

For the ATLAS experiment the integrated luminosity for each year can be seen in figure 3.4a as well as an example of the instantaneous luminosity for the choosen year in figure 3.4b.

(a) Integrated Luminosity 2011 - 2018 (b) 2018 Peak Instantaneous Luminosity

Figure 3.4: Luminosity is monitored as both a running total known as the Integrated Luminosity as depicted in (a) and as an instantaneous quantity as shown in (b)

3.4 Pile-up at the LHC

Given the large number of protons per bunch and the cross-section of a proton-proton interaction, the probability to observe multiple interactions per bunch crossing is quite high. These multiple-interaction are known as pile-up, μ or the time averaged representation $\langle\mu\rangle$, and come in two different forms:

1. **In-time pile-up:** These are the other proton-proton collisions that occur during the same bunch crossing as the primary interaction that caused the Data Acquisition (DAQ) system to trigger. These are the standard extra interactions we expect to observe as stated above.
2. **Out-of-time pile-up:** These are interactions that occur either before or after a

295 bunch crossing that causes the DAQ to trigger. This effect is generally due to the
 296 long integration times of some detector electronics.

Figure 3.5: Pileup for data taking periods 2015 - 2018

297 The pile-up profile for past years can be seen in figure 3.5. The width of this distributino
 298 is due a combination of Poissonian statistics, the decrease in number of protons per bunch
 299 over the lifetime of a single run, and optimization tweaks to the beam's profile during
 300 runtime. Understanding and eliminating the noise from these pile-up events is crucial
 301 to reconstructing physics variables to represent the primary interaction we hope to
 302 observe.

303 Chapter 4

304 The ATLAS Detector

305 Given the immense energies available at the LHC, and the veritable zoo of particles we
306 are trying to detect, we require a general-purpose experiment in order to fully exploit
307 the full range of physics opportunities provided. Two international collaborations rose
308 to this challenge, the CMS (Compact Muon Solenoid) and ATLAS (A Torroidal LHC
309 ApparatuS) experiments. While both have similar physics goals and each of them
310 strengths and weaknesses, this dissertation will focus on the ATLAS experiment and
311 the intricacies of its three main sub-detectors and two massive magnet systems depicted
312 in figure 4.1.

313 Originally proposed in 1994 the ATLAS experiment was completed in 2008. On July
314 4th, 2012 in a joint announcement the ATLAS and CMS experiments announced the
315 discovery of the long predicted Higgs Boson. The collaboration now boasts over 3000
316 physicists from 175 institutions spread across 38 countries and continues to probe

Figure 4.1: [3] Here we see a cut-away side view of the ATLAS detector with the major components labeled. Note that within each of these labeled components there may exist multiple different detector technologies. For scale two people in red are shown standing between the disk muon chambers on the left side of the figure.

317 the limits of the Standard Model in pursuit of answers to some of Humanities deepest
318 questions.

319 Located approximately 100 meters underground in a vast excavated chamber, the AT-
320 LAS detector rests its 7000 metric tonnes on a bed of concrete reinforced steel. Out of
321 it flows the signals of over 100 million electronic channels through a zip tied mass of
322 greater than 3000 kilometers of cabling. At its very center is one of the four interaction
323 points of the LHC, specifically Point 1, where the two counter circulating proton beams
324 are skillfully shaped and then collided by a series of magnets. The energetic particles
325 resultant from this collision then fly out in all directions into the bulk of the ATLAS
326 detector.

327 The first sub-system they meet is the Inner Detector (ID) and its many layers of strip
328 and pixel silicon detectors along with a transition radiation gaseous wire detector, all
329 bathed in the 2T magnetic field of the surrounding superconducting solenoidal magnet.
330 This system exploits the ionization of charged particles to track their curved trajectory
331 through the magnetic field. This curvature gives us charge information, a momentum
332 measurement, and precision 3D vertices crucial to the identification of the secondary
333 vertices of a b-hadron decay.

334 Outside of the solenoid the particles are faced with first the Electromagnetic and then
335 the Hadronic sampling calorimeters. Here, layers of scintillator and high radiation length
336 materials are implemented to measure the energy of electrons, photons, and hadrons.
337 As the goal is to completely absorb the energy of all outgoing particles the calorimeter

338 has a nearly 4π solid angle coverage.

339 Finally we have the muon system surrounding the calorimeter and equipped with its
340 own torroidal magnet system. Here the charged muon bends in the magnetic field
341 while leaving a trail of ionization in the muon spectrometer before exiting the detector
342 completely. Neutrinos are the only other standard model particle that leave the detector,
343 however they do so without detection. A depiction of the various particle interactions
344 with the different detector sub-systems can be seen in figure 4.2

345 In the following sections I will explain our choosen coordinate system and give a more
346 detailed reveiw of these 3 detector sub-systems.

347 4.1 ATLAS Coordinate System

348 Using the nominal interaction point as the origin, ATLAS uses a right handed coor-
349 dinate system where the positive x -axis points towards the center of the LHC ring,
350 the positive y -axis points upwards, and the positive z -axis is defined by the counter
351 clockwise circulating beam direction as viewed from above shown in figure 4.3 [3].

352 Using these coordinates we can define the physical momentum of the objects measured
353 as $\vec{p} = (p_T, p_z)$ with p_T being the momentum of the object in the transverse plane and
354 p_z the momentum along the beam axis. Given the cylindrical symmetry of ATLAS it
355 is desireable to define the polar angle θ from the beam axis with the $r - \phi$ plane being
356 perpendicular to that axis. Since the particles we observe are relativistically boosted

Figure 4.2: This slice of the ATLAS detector depicts how different particles interact with each component of the detector it crosses. A dashed line indicates no interaction while a solid line indicates interaction. Electrons (yellow/green) and charged hadrons (red) interact with the tracker and curve in the solenoid's magnetic field. Electrons and photons (yellow/green) are absorbed by the Electromagnetic calorimeter. All hadrons (red/yellow) are absorbed by the Hadronic calorimeter. The muons (orange) curve in both the solenoid and torroid magnetic fields before exiting the detector. Finally, the neutrinos (white) pass through the entire detector without interacting.

Figure 4.3: [4] A cartoon view of the the LHC from above showing the SPS, LHC and the four main experiments of the LHC: ATLAS, CMS, LHCb, and ALICE. The standard cartesian coordinate system is shown with its origin at the ATLAS interaction point, the positive x -axis towards the center of the LHC, the positive y -axis pointing upwards, and the positive z -axis pointing along the beamline towards the "A-side"

357 in the z -axis it is desirable to use the Lorentz invariant quantity pseudorapidity (η)
 358 defined in terms of the polar angle by

$$\eta = -\ln \tan \left(\frac{\theta}{2} \right). \quad (4.1)$$

359 where $\eta = 0$ is in the $x - y$ plane and larger values of $|\eta|$ being closer to the beam axis
 360 as can be seen in figure 4.4.

Figure 4.4: Modified from [4] this cartoon represents a selection of pseudorapidity (η) values overlaid with some cartesian coordinates (dashed black lines). The redlines are drawn for $\eta = \pm 0.5, 1.0, 3.0$

361 In this analysis the angular separation between objects in the detector is calculated and
 362 represented using the geometric quantity

$$\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} \quad (4.2)$$

4.2 Tracking with the Inner Detector

With its closest component, the insertable b-layer (IBL) [5], only 3.3 cm from the interaction point The Inner Detector (ID), shown in figure 4.5 [6, 7], faces the incredible challenge of providing precision momentum resolution and identification of both primary and secondary vertex measurements of charged tracks all while receiving the highest fluence.

Figure 4.5: [5] Diagram of inner detector

It is designed to be very compact to reduce the probability of a particle decaying inside and to give precision measurements of the particles curvature in the 2T solenoidal

371 magnetic field. This leads to excellent momentum resolution above the nominal p_T
 372 threshold of 0.5 GeV and within the pseudorapidity range of $|\eta| < 2.5$ as shown in figure
 373 4.6

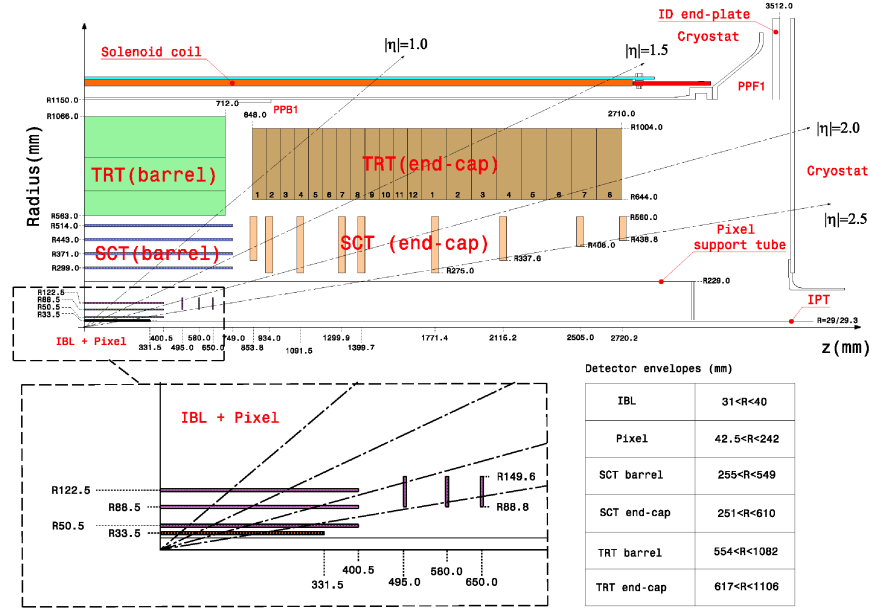

Figure 4.6: [8] Schematic of the Inner Detector including eta lines. Each component shown is cylindrically symmetric leading to a multi-layered detector.

374 The ID is composed of three different detector technologies for particle trajectory re-
 375 construction: The Pixel Detector, Semiconductor Tracker (SCT) and the Transition
 376 Radiation Tracker (TRT). These will be discussed in the following sections.

377 4.2.1 Pixel Detector

378 The ATLAS Pixel Detector [3], the innermost subdetector of the ID, is designed to
379 give the best resolution possible as close as possible to the interaction point. This
380 is accomplished using the 4 barrel layers and the 3 disks per endcap as indicated in
381 figure 4.6. The inner most barrel layer, the IBL, has pixel dimensions of $50\mu\text{m}(\hat{\phi}) \times$
382 $250\mu\text{m}(\hat{z}) \times 200\mu\text{m}(\hat{r})$. For the other layers the dimensions are $50\mu\text{m}(\hat{\phi}) \times 400\mu\text{m}(\hat{z})$ for
383 about 90% of the pixels and $50\mu\text{m}(\hat{\phi}) \times 600\mu\text{m}(\hat{z})$ for the others, all with a thickness
384 of $250\mu\text{m}(\hat{r})$. This gives a total active area of 1.88m^2 collected through 92.4 million
385 readout channels, more than half of the total number of channels for ATLAS. This
386 detailed charged particle information very close to the interaction point is crucial not
387 only for pattern recognition for track reconstruction, but also for the reconstruction
388 of the primary and secondary vertices intrinsic to the decay of a b -hadrons, a critical
389 element of the analysis presented in this thesis.

390 4.2.2 Semiconductor Tracker

391 Encompassing the Pixel Detector, the Semiconductor Tracker (SCT) [3] is composed of
392 double sided silicon microstrips modules. Each side of the 4088 modules is constructed
393 out of two silicon strip sensors that are daisy chained together. The result is 768
394 composite strips each 12.6cm with an inter-strip pitch of $80\mu\text{m}$. In the barrel the strips
395 are aligned with the \hat{z} direction, while in the end caps they are aligned with the \hat{r}
396 direction. In both cases the separation of the strips is constant in $\hat{\phi}$. The two sides are

397 rotated with respect to each other by $40\mu\text{m}$ to allow for position measurement along the
 398 length of the strip. These modules are then used to tile the 4 barrel layers and 9 disks
 399 per endcap (18 disks in total) as seen in figure 4.6. This design is chosen to ensure
 400 that each charged track interacts with 8 strip layers (equivalent to four space points).
 401 This information is used to further measure the momentum and impact parameter, and
 402 as well as vertex identification of charged particles.

403 **4.2.3 Transition Radiation Tracker**

404 The Transition Radiation Tracker [3], the outermost subdetector of the ID, provides
 405 tracking through the detection of transition radiation from ultra-relativistic charged
 406 particles for $\eta < 2.0$ using 350,000 drift tube channels also known as straws. The
 407 4mm diameter straws are filled with a 70% Xe, 27% CO₂, and 3% O₂ gas mixture
 408 and a $31\mu\text{m}$ diameter gold-plated tungsten wire anode at the center for the collection
 409 of the ionization signal. In the barrel 73 azimuthally symmetric layers of 144cm straws
 410 are oriented parallel to the beam pipe with an electrical division in the center of each
 411 allowing the two sides to be read out separately. For each endcap the straws are radially
 412 oriented in 160 symmetric planes each containing 768 37cm long drift tubes shown
 413 in figure 4.6. In both the barrel and the end caps polypropylene fibers (barrel) or
 414 foils (encaps) function as the transition radiation material which causes the relativistic
 415 charged particles to radiate and thus ionize the gas in the straw. The amount of
 416 transition radiation produced is proportional to the Lorentz factor meaning that lighter

417 particles (e.g. electrons) will produce more radiation. Thus, by defining a high and low
 418 threshold, we can identify tracks belonging to electrons by requiring they register more
 419 high-threshold hits. There are typically 36 TRT hits per charged track.

420 4.3 Calorimetry

Figure 4.7: [3] A cutaway diagram of ATLAS's sampling calorimeters

421 Once the proton collision remnants have passed through the ID and it's surround-
 422 ing solenoid they enter into the ATLAS calorimeters depicted in figure 4.7. Sampling
 423 calorimeter technologies were choosen for their compact geometry and lower cost point.
 424 These are constructed by alternating layers of absorber, a dense material which reduces
 425 the incedent particles energy, and active material which produces a detectible signal
 426 when a partilce passes through. This means that the detected signal is only a fraction

427 of the total energy of the particle and thus requires a study of the calorimeter response
 428 for calibration purposes [9]. The first system, the Electromagnetic Calorimeter (EMC),
 429 is designed to measure the energy of electrons and photons which primarily lose their
 430 energy via bremsstrahlung and pair production electromagnetic interactions. Outside of
 431 the EMC is the Hadronic Calorimeter (HC) which is designed to measure the energy of
 432 jets of hadrons through their electromagnetic and strong interactions. These detectors
 433 cover the entire $|\eta| < 4.9$ range and provide complete containment of both Electromag-
 434 netic and Hadronic showers with higher granularity in the EMC for $|\eta| < 2.5$, the region
 435 matched to the ID, for precision measurements of electrons and photons. By instrument-
 436 ing this huge space in $|\eta|$ we can search for events with asymmetric energy deposits which
 437 imply the existence of a particle we didn't detect represented by missing transverse
 438 energy E_T^{miss} .

439 **4.3.1 Electromagnetic Calorimeter**

440 The innermost calorimeter, the Liquid Argon (LAr) Electromagnetic Calorimeter (EMC)
 441 [3], uses lead as the absorber and liquid argon as the active material in an "accordion
 442 geometry" as seen in figure 4.8. This geometry was chosen for uniform coverage in
 443 $\hat{\phi}$ due to its lack of un-instrumented cracks in the radial direction. The barrel region
 444 covers $|\eta| < 1.475$ and an end cap on each side covers $1.375 < |\eta| < 3.2$ each housed
 445 in their own cryostat. The barrel is composed of two half barrels with a 4mm gap at
 446 $z = 0$ and both end caps are divided into an inter wheel covering $2.5 < |\eta| < 3.2$ and

447 an outer wheel covering $1.375 < |\eta| < 2.5$.

Figure 4.8: [3] Sketch of LAr EMC barrel module where the lead and liquid argon layers are visible in an accordion like geometry. Looking from the foreground to the back there are 3 different types of cells visible.

448 In the $|\eta| < 2.5$ region the EMC has 3 radial layers for precision physics measure-
 449 ments. Layer 1 consists of strip cells which are finely segmented with $\Delta\eta = 0.0031$
 450 and $\Delta\phi = 0.0245$ allowing for precision position resolution which gives discrimination
 451 power between a single γ deposit and the π^0 characteristic $\gamma\gamma$ deposit. Layer 2 , which
 452 collects the largest fraction of energy from electromagnetic shower, is segmented with

453 $\Delta\eta = .025$ and $\Delta\phi = 0.0245$. Layer 3 collects the tail of the electromagnetic shower
 454 using a coarser segmentation of $\Delta\eta = .05$ and $\Delta\phi = 0.0245$. Additionally, in the region
 455 $|\eta| < 1.8$ a thin pre-sampler , which contains no lead absorber, was placed in front of
 456 Layer 1 to allow for energy corrections due to losses upstream of the EMC. Combined
 457 the EMC is > 22 radiation lengths (X_0) in the barrel and $> 24 X_0$ in the end-caps,
 458 where a radiation length is the average distance an electron travels in a given material
 459 before losing $1/e$ of its original energy E_0 via bremsstrahlung radiation.

460 **4.3.2 Hadronic Calorimeter**

461 Directly outside the EMC envelope is the Hadronic Calorimeter (HC) system [3] which
 462 consists of three sampling calorimeter technologies: the Tile calorimeter, the LAr
 463 hadronic end-cap calorimeter (HEC) and the LAr forward calorimeter (FCal). Com-
 464 bined, these three subsystems give measurements of hadronic jet energies in the $0 <$
 465 $|\eta| < 4.9$ range. The tile calorimeter uses steel as the absorber layer and scintillating
 466 tiles as the active material and covers the region $|\eta| < 1.7$ with a barrel section flanked
 467 by two barrel extensions each divided azimuthally into 64 modules. These scintillator
 468 tiles are read out on two sides by wave-length shifting fibers connected to photomul-
 469 tiplier tubes as seen in figure 4.9. At $\eta = 0$ the total tile calorimeter thickness is 9.7
 470 nuclear interaction lengths (λ), where λ is the average distance a hadron travels before
 471 interacting inelastically with a nucleus.

472 The HEC is composed of two independent wheels per end-cap located just past the

Figure 4.9: [3] Schematic of a tile calorimeter module including a depiction of the connection between the scintillator tile to the photomultiplier via a wavelength-shifting fibre.

473 EMC end-cap but sharing the same cryostat. This system uses copper as an absorber
 474 and liquid argon for the active material and covers the $1.5 < |\eta| < 3.2$ range using
 475 32 wdg-shaped modules per wheel. Finally, the FCal shares the same cryostat as the
 476 EMC and HEC end-caps and acts to extend the coverage of the combined calorimeter
 477 system to include the $3.1 < |\eta| < 4.9$ range. Each endcap contains 3 modules, the first
 478 an electromagnetic module (Copper/Liquid-Argon) which is followed by two hadronic
 479 modules which use (Tungsten/Liquid-Argon).

480 **4.4 Muon Spectrometer**

481 The ATLAS Muon Spectrometer (MS) [3], see figure 4.10, accomplishes tracking of
 482 charged particles in the $|\eta| < 2.7$ region for momentum reconstruction while also provid-
 483 ing triggering on charged particles in the $|\eta| < 2.4$ region. The magnetic field necessary
 484 for momentum reconstruction is provided by 3 air core torroid systems, one barrel tor-
 485 roid covering $|\eta| < 1.4$ and two endcap torroid systems which are inserted into the inner
 486 radius of the the barrel torroid to cover the $1.6 < |\eta| < 2.7$. The so called transition
 487 region $1.4 < |\eta| < 1.6$ between these two magnet systems is covered by a combination
 488 of the barrel and endcap torroid magnets. Similar to the ID the resolution is inversely
 489 proportional to the particle's incident momentum. Any muon with pT lower than 3GeV
 490 will never make it to the MS and thus will not be detected.

491 Precision tracking measurements for momentum reconstruction is accomplished using

Figure 4.10: [3] A cut-away diagram of the ATLAS muon system and its many sub-detectors.

492 the Monitored Drift Tube chambers (MDTs) for $|\eta| < 2.0$ and using Cathode-Strip
493 Chambers (CSCs) for $2.0 < |\eta| < 2.7$. The MDT system consists of 1163 drift tube
494 chambers arranged in three to eight layers for varying η . The CSCs are designed to
495 withstand the higher rate and retain good time resolution using multiwire proportional
496 chambers with orthogonal segmented cathode planes.

497 The MS also gives nanosecond tracking information for triggering on muon tracks. This
498 is accomplished using Resistive Plate Chambers (RPC) in the barrel region $|\eta| < 1.05$
499 and Thin Gap Chambers (TGC) in the end-cap $1.05 < |\eta| < 2.4$ region. Both chamber
500 systems deliver a triggerable signal with a spread of 15–25 ns, thus providing the ability
501 to tag individual beam-crossings.
